OVERVIEW

The media have an important role to play in communicating about one of the most complex challenges facing global polio eradication efforts: the spread of circulating vaccine-derived poliovirus (cVDPV) outbreaks in areas where immunization rates are low. This guide is intended to support media reporting on cVDPVs to ensure coverage does not inadvertently cause vaccine hesitancy, mistrust, or other unintended adverse consequences to public health and use of polio vaccines. Vaccination efforts that achieve and maintain a high level of coverage (85% or higher) within at-risk populations are critical to stopping all forms of polio and finally achieving eradication of the disease.

CVDPVS: ASKED AND ANSWERED

What are cVDPVs? A child cannot get cVDPV infection from receiving a polio vaccine. cVDPVs emerge when not enough children are vaccinated against polio, and the weakened strain of the poliovirus contained in the oral polio vaccine (OPV) circulates among under-immunized populations for a long time in areas with poor sanitary conditions. The weakened strains are shed by vaccinated children into the environment via their digestive systems and can pass from one unvaccinated individual to another, a process exacerbated by poor sanitation systems and the absence of clean drinking water. Over time, genetic changes in the virus can result in reversion to a form that can cause paralysis. cVDPVs are different from wild polioviruses, which now only circulate in Pakistan and Afghanistan. The rise in cVDPV cases, however, poses a risk to children, threaten eradication efforts and, just like wild polio, must be stopped.

What causes cVDPV outbreaks? cVDPV outbreaks are caused by community-level immunity gaps, where both routine immunization and door-to-door campaigns have failed to reach some children for many years. These gaps could be due to several factors, such as weak routine immunization programs, poor campaign quality, insecurity and civil conflict, vaccine hesitancy due to misinformation,
and issues accessing high-risk groups such as mobile populations. About 90% of cVDPV outbreaks are caused by type 2 cVDPV.

- In 2020, the March-July suspension of polio campaigns to protect communities and staff from COVID-19, coupled with related disruptions to routine immunization, created immunity gaps that led to new outbreaks of cVDPVs and further increased transmission of cVDPVs globally.

**Where are outbreaks happening?** Most cVDPV outbreaks are in Africa, although there are also cases in parts of Asia, the Middle East and Eastern Europe. For the latest cVDPV case counts, see the GPEI’s cVDPVs page.

**How are outbreaks stopped?** As with wild polio, outbreaks of cVDPVs are stopped by ensuring every child is reached with oral polio vaccine through high-quality immunization campaigns to close immunity gaps. Fast, high-quality vaccination campaigns using type 2 monovalent OPV (mOPV2) have stopped cVDPV2 outbreaks previously. The vaccine continues to be a safe, effective tool for outbreak response across the continent. In addition, the novel oral polio vaccine type 2 (nOPV2) is now being rolled out in several countries affected by cVDPV2 to help more sustainably stop outbreaks.

---

**FICTION VS. FACT**

There are several common misconceptions about cVDPVs, leading to the proliferation of misinformation that can reduce vaccine confidence and contribute to hesitancy and refusals. Journalists who are writing about polio can help to be a part of the solution and address these misconceptions in their stories.

<tbody>
<tr>
<td>A child can get cVDPV infection or be paralyzed from receiving OPV.</td>
<td>A child cannot get cVDPV from receiving OPV. A child can get cVDPV if they are not immunized against polio and live in an area where cVDPV is circulating. Vaccination against polio will protect an individual from cVDPV.</td>
</tr>
<tr>
<td>OPV is inferior to IPV (inactivated polio vaccine).</td>
<td>OPV is a safe, inexpensive, easy to administer and extremely effective vaccine that can stop person-to-person transmission of poliovirus by providing both individual and community-level protection, making it an important tool for cVDPV outbreak response in low-resource settings. OPV stimulates good gut immunity in the vaccinated child. Additionally, for the first several weeks after receiving OPV, a vaccinated child can excrete the weakened virus from the vaccine in their stool and spread it to their close contacts in areas with poor hygiene and sanitation, resulting in 'passive' immunization of unvaccinated people. However, if the weakened virus circulates unchecked for a long time in an under-immunized population, it can revert to a form that causes paralysis. IPV prevents paralysis but cannot prevent person-to-person transmission of polio and is more difficult to administer in low resource settings, due to both the cost of the vaccine and the need for a trained health worker to deliver it via injection. It may be used in combination with OPV in endemic and high-risk countries but cannot stop outbreaks alone.</td>

**EXAMPLES OF COMPREHENSIVE EDITORIAL EXPLANATIONS OF CVDPVS**

These examples from published stories clarify that cVDPVs are different from wild polioviruses and can only mutate from the weakened virus used in OPV in under-immunized populations. They also help underline that children cannot contract cVDPV from receiving the vaccine.

“...When they went back to their communities, Dr. Mkanda said, the vaccine went through their digestive systems and out into the environment, and other children, who had not been inoculated, could then pick it up and also become immune...

...Very rarely, however, the vaccine virus can mutate back into something resembling the wild kind. If that vaccine-derived mutation keeps spreading because nearby villages are not fully vaccinated, it can, in a few cases — about one infection in 200 — paralyze people. The name of the polio strain may give the impression that people contract it from vaccinations, but that is not the case.”

“...But in a number of countries where too few children had been vaccinated against polio, the type 2 vaccine viruses continued to circulate among susceptible children. When polio vaccine viruses cycle through enough children, they can regain the power to paralyze.”

— Helen Branswell, *STAT*, October 21, 2019
